ABSTRACT

We present the implementation of turbulence transport equations in addition to the Reynolds-averaged MHD equations within the CRONOS framework. The model is validated by comparisons with earlier findings before it is extended to be applicable to regions in the solar wind that are not highly super-Alfvénic. We find that the respective additional terms result in absolute normalized cross-helicity to decline more slowly, while a proper implementation of the mixing terms can even lead to increased cross-helicities in the inner heliosphere.

The model extension allows to place the inner boundary of the simulations closer to the Sun, where we choose its location at 0.1 AU for future application to the Wang-Sheeley-Arge model. Here, we concentrate on effects on the turbulence evolution for transient events by injecting a coronal mass ejection (CME). We find that the steep gradients and shocks associated with these structures result in enhanced turbulence levels and reduced cross-helicity. Our results can now be used straightforwardly for studying the transport of charged energetic particles, where the elements of the diffusion tensor can now benefit from the self-consistently computed solar wind turbulence. Furthermore, we find that there is no strong back-reaction of the turbulence on the large-scale flow so that CME studies concentrating on the latter need not be extended to include turbulence transport effects.

Subject headings: magnetohydrodynamics (MHD) — turbulence — shock waves — solar wind — methods: numerical — Sun: heliosphere — Sun: magnetic fields

1. Introduction

In a recent publication (Wiengarten et al. 2014) we presented results for inner-heliospheric solar wind conditions from simulations based on observational boundary conditions derived from the Wang-Sheeley-Argge (WSA, Arge & Pizzo (2000)) model. The obtained 3D configurations provide the basis for subsequent studies of energetic particle transport. For a long time, the standard approach to couple the solar wind dynamics to the transport of charged energetic particles has been to parameterise all transport processes in terms of ‘background’ quantities such as the large-scale solar wind velocity and heliospheric magnetic field strength. This was particularly true for the treatment of spatial diffusion (see, e.g., Potgieter 2013). Only in recent years so-called *ab-initio* models were developed, in which the diffusion coefficients are formulated explicitly as functions of small-scale, low-frequency turbulence quantities such as the magnetic field fluctuation amplitude or the correlation length (e.g., Parhi et al. 2003; Pei et al. 2010; Engelbrecht & Burger 2013). This significant improvement has been possible, on the one hand due to the development of turbulence transport models that, most often, describe the evolution of turbulent energy density, cross-helicity, and correlation lengths for low-frequency turbulence, as observed in the solar wind, with increasing distance from the Sun, see, e.g., the review in Zank (2014). On the other hand, our present-day knowledge about turbulence in the solar wind (see, e.g., the reviews by Matthaeus & Velli 2011; Bruno & Carbone 2013) has increased tremendously since the first measurements (Coleman 1968; Belcher & Davis 1971) thanks to highly sophisticated analyses (e.g., Horbury et al. 2008, 2012).

After the pioneering papers by Tu et al. (1984) and Zhou & Matthaeus (1990a,b,c) and first systematic studies of the radial evolution of turbulence quantities (Zank et al. 1996), major progress has only been achieved in recent years. First, Breech et al. (2008) improved the previous modeling by considering off-ecliptic latitudes. Second, in Usmanov

et al. (2011) this turbulence model was extended to full time dependence and three spatial dimensions. In the same paper the turbulence evolution equations were simultaneously solved along with a large-scale MHD model of the supersonic solar wind. While Usmanov et al. (2012, 2014) extended this study further with the incorporation of pick-up ions and electrons as separate fluids, as well as an eddy-viscosity approximation to self-consistently account for turbulence driven by shear, Oughton et al. (2011) undertook another extension of the modeling by considering not only one but two, mutually interacting, incompressible components, namely quasi-two-dimensional turbulent and wave-like fluctuations. The effect on turbulence due to changing solar wind conditions in the outer heliosphere during the solar cycle have recently been addressed by Adhikari et al. (2014).

All of the mentioned models have one limitation in common, namely the condition that the Alfvén speed V_A is significantly lower than that of the solar wind U , which precludes their application to the heliocentric distance range below about 0.3 AU. The turbulence in this region and its consequences for the dynamics of the solar wind have been studied on the basis of the somewhat simplified transport equations for the wave power spectrum and the wave pressure (e.g., Tu & Marsch 1995; Hu et al. 1999; Vainio et al. 2003; Shergelashvili & Fichtner 2011). The Alfvén speed limitation in the more detailed models was very recently removed with a new, comprehensive approach to the general problem of the transport of low-frequency turbulence in astrophysical flows by Zank et al. (2012), see also Dosch et al. (2013). Not only are the derived equations formally valid close to the Sun in the sub-Alfvénic regime of the solar wind, but they also represent an extension of the treatment of turbulence by non-parametrically and quantitatively considering the evolution of the so-called energy difference in velocity and magnetic field fluctuations, and by explicitly describing correlation lengths for sunward and anti-sunward propagating fluctuations as well as for the energy difference (sometimes also referred to as the residual energy).

In our previous modeling (Wiengarten et al. 2014) we derived inner boundary conditions beyond the Alfvénic critical point at 0.1 AU by means of the WSA model. This approach matches a potential field solution for the coronal magnetic field to the observed photospheric magnetograms, and the resulting magnetic field topology can be linked empirically to the corresponding solar wind speed for every open field line (Wang & Sheeley 1990). We performed simulations of the inner-heliospheric solar wind conditions for several Carrington rotations. Subsequently, the resulting time-dependent 3D configuration is used to study the transport of charged energetic particles by means of stochastic differential equations (A. Kopp, priv. comm.). Within that study, the transport coefficients required for the latter model have so far been estimated from the large-scale quantities provided by the ideal MHD equations (see discussion above). In order to obtain more realistic transport coefficients for the study of propagation of charged energetic particles, we extend our previous modeling by solving the 3D time-dependent turbulence transport equations self-consistently coupled to the Reynolds-averaged MHD equations. Such an approach was taken by Usmanov et al. (2011) and will provide the starting point for our modeling. In a first step we validate our implementation by comparing with these authors’ findings. The turbulence transport equations used there can also be obtained from the more general turbulence transport equations of Zank et al. (2012) by applying respective simplifications. The Usmanov model neglects the Alfvén velocity and is therefore only applicable to highly-super-Alfvénic solar wind regimes and we remove this constraint by retaining the respective terms of the more general Zank model. This extension to the model allows us to place the inner boundary of the simulations closer to the Sun, for which we choose 0.1 AU for future couplings to the WSA model. A correction of the model is also required with regard to the inappropriate absence of turbulence driving by shear, which has only recently been addressed by Usmanov et al. (2014). Here, we will follow earlier simple ad-hoc approaches as in Zank et al. (1996) and Breech et al. (2008). This improvement is essential for the application to solar wind

transients, such as coronal mass ejections (CMEs), which we address in the second part of this paper.

With this application to the propagation of coronal mass ejections (CMEs) we extend earlier approaches towards a self-consistent treatment of the expansion of the disturbed solar wind. Such a treatment is desirable because it has been realized that a proper modeling of CMEs requires a realistic model for the ‘background’ solar wind (e.g., Jacobs & Poedts 2011; Lee et al. 2013). If one does not resort to empirical solar wind background models (like Cohen et al. 2007), one needs to model the solar wind turbulence explicitly (Sokolov et al. 2013). Besides the importance of a self-consistent incorporation of the turbulence evolution in the solar wind for CME propagation studies (see also van der Holst et al. 2014), the generation of turbulence by large-scale disturbances is of interest for energetic particle transport studies at interplanetary shocks (e.g., Sokolov et al. 2009). While a self-consistent turbulence incorporation into a model of the supersonic solar wind out to 100 AU including corotating interaction regions has been achieved by Usmanov et al. (2012), corresponding studies for the case of CMEs are still limited to the most inner heliosphere inside about 30 solar radii (Jin et al. 2013). These studies use, compared to the approaches developed by Oughton et al. (2011), Usmanov et al. (2012), or Zank et al. (2012), simplified equations for the treatment of the turbulence evolution. We extend the modeling here by both employing a refined treatment of the turbulence evolution and solving the self-consistent model equations out to 1.2 AU.

The paper is organized as follows: In Section 2 we present the turbulence transport equations and the respective coupling to the ideal MHD equations. Details are outsourced to the Appendix. Section 3 is used to validate our implementation by comparing with the respective results of Usmanov et al. (2011). We present the extensions we apply to the model and demonstrate their effects in Section 4. In Section 5 we move the inner boundary

closer to the Sun and show results for both quiet and CME-disturbed cases. We conclude with a summary and an outlook on future improvements in Section 6.

2. Equations and Code Setup

We follow the approach of Usmanov et al. (2011) to incorporate the evolution equations of small-scale turbulence quantities into the framework of the MHD code CRONOS (see Appendix C for details concerning the code). As we will seek to inject coronal mass ejections at an inner boundary of 0.1 AU, the assumption of highly-super-Alfvénic solar wind conditions is not justifiable everywhere. The turbulence transport equations are extended to keep terms associated with the Alfvén velocity, which can be derived from a simplified model by Zank et al. (2012) (see Appendix A), while we employ the coupling between small-scale and large-scale equations as given in Usmanov et al. (2011). The turbulence transport equations for the considered case then are :

$$\begin{aligned} \partial_t Z^2 + \nabla \cdot (\mathbf{U} Z^2 + \mathbf{V}_A Z^2 \sigma_C) &= \frac{Z^2(1 - \sigma_D)}{2} \nabla \cdot \mathbf{U} + 2\mathbf{V}_A \cdot \nabla (Z^2 \sigma_C) + Z^2 \sigma_D \hat{\mathbf{B}} \cdot (\hat{\mathbf{B}} \cdot \nabla) \mathbf{U} \\ &\quad - \frac{\alpha Z^3 f^+(\sigma_C)}{\lambda} + \langle \mathbf{z}^+ \cdot \mathbf{S}^+ \rangle + \langle \mathbf{z}^- \cdot \mathbf{S}^- \rangle \end{aligned} \quad (1)$$

$$\begin{aligned} \partial_t (Z^2 \sigma_C) + \nabla \cdot (\mathbf{U} Z^2 \sigma_C + \mathbf{V}_A Z^2) &= \frac{Z^2 \sigma_C}{2} \nabla \cdot \mathbf{U} + 2\mathbf{V}_A \cdot \nabla Z^2 + Z^2 \sigma_D \nabla \cdot \mathbf{V}_A \\ &\quad - \frac{\alpha Z^3 f^-(\sigma_C)}{\lambda} + \langle \mathbf{z}^+ \cdot \mathbf{S}^+ \rangle - \langle \mathbf{z}^- \cdot \mathbf{S}^- \rangle \end{aligned} \quad (2)$$

$$\begin{aligned} \partial_t (\rho \lambda) + \nabla \cdot (\mathbf{U} \rho \lambda) &= \rho \beta \left[Z f^+(\sigma_C) - \frac{\lambda}{\alpha Z^2} (\langle \mathbf{z}^+ \cdot \mathbf{S}^+ \rangle (1 - \sigma_C) + \langle \mathbf{z}^- \cdot \mathbf{S}^- \rangle (1 + \sigma_C)) \right] \end{aligned} \quad (3)$$

with $f^\pm := \sqrt{1 - \sigma_C^2} [\sqrt{1 + \sigma_C} \pm \sqrt{1 - \sigma_C}]$ where the following moments of the Elsässer variables (described below) are used:

$$Z^2 := \frac{\langle \mathbf{z}^+ \cdot \mathbf{z}^+ \rangle + \langle \mathbf{z}^- \cdot \mathbf{z}^- \rangle}{2} = \langle u^2 \rangle + \langle b^2/\rho \rangle \quad (4)$$

$$Z^2 \sigma_C := \frac{\langle \mathbf{z}^+ \cdot \mathbf{z}^+ \rangle - \langle \mathbf{z}^- \cdot \mathbf{z}^- \rangle}{2} = 2 \langle \mathbf{u} \cdot \mathbf{b} / \sqrt{\rho} \rangle \quad (5)$$

$$Z^2 \sigma_D := \langle \mathbf{z}^+ \cdot \mathbf{z}^- \rangle = \langle u^2 \rangle - \langle b^2/\rho \rangle . \quad (6)$$

Here, Z^2 is twice the total energy per unit mass of the fluctuations, σ_C is the normalized cross-helicity, σ_D is the normalized difference between the magnetic and kinetic energy of the fluctuations per unit mass, also known as residual energy. As done in previous studies, we assume an observationally inferred constant value for the energy difference $\sigma_D = -1/3$ (Tu & Marsch 1995) and reserve an extension to include a variable energy difference (Zank et al. 2012) for future studies. Furthermore, λ is the correlation length, $\mathbf{V}_A = \mathbf{B}/\sqrt{\rho}$ is the normalized Alfvén velocity, $\alpha = 2\beta = 0.8$ are the Karman-Taylor constants, and terms involving sources of turbulence $\mathbf{S}^\pm$ are discussed in subsequent sections.

The Elsässer variables $\mathbf{z}^\pm := \mathbf{u} \pm \mathbf{b}/\sqrt{\rho}$, where $\mathbf{u}$ and $\mathbf{b}$ denote the fluctuations about the mean fields $\mathbf{U}$ and $\mathbf{B}$, describe the inward ($\mathbf{z}^+$) and outward ($\mathbf{z}^-$) propagating modes with respect to the mean magnetic field so that $\mathbf{z}^\pm$ is anti-parallel/parallel to it. $\hat{\mathbf{B}}$ denotes the unit vector in the direction of the mean magnetic field.

The turbulence transport equations (1) – (3) are implemented in the framework of the CRONOS code as additional equations to be solved alongside the Reynolds-averaged, normalized ideal MHD equations in the co-rotating frame of reference with respective coupling terms to account for the effects of turbulence on the large-scale MHD quantities in

analogy to Usmanov et al. (2011):

$$\partial_t \rho + \nabla \cdot (\rho \mathbf{V}) = 0 \quad (7)$$

$$\partial_t (\rho \mathbf{U}) + \nabla \cdot [\rho \mathbf{V} \mathbf{U} + \bar{p} \mathbf{1} - \eta \mathbf{B} \mathbf{B}] = -\rho (\mathbf{g} + \boldsymbol{\Omega} \times \mathbf{U}) \quad (8)$$

$$\partial_t \mathbf{B} + \nabla \cdot (\mathbf{V} \mathbf{B} - \mathbf{B} \mathbf{V}) = 0 \quad (9)$$

$$\begin{aligned} \partial_t e + \nabla \cdot [e \mathbf{V} + (p + |\mathbf{B}|^2/2) \mathbf{U} - (\mathbf{U} \cdot \mathbf{B}) \mathbf{B} - \mathbf{V}_A \rho Z^2 \sigma_C / 2 + \mathbf{q}_H] = \\ - \rho \mathbf{V} \cdot \mathbf{g} - \mathbf{U} \cdot \nabla p_w - \frac{Z^2 \sigma_C}{2} \mathbf{V}_A \cdot \nabla \rho + \frac{\rho Z^3 f^+(\sigma_C)}{2\lambda} \\ + \mathbf{U} \cdot (\mathbf{B} \cdot \nabla) [(\eta - 1) \mathbf{B}] - \rho \mathbf{V}_A \cdot \nabla (Z^2 \sigma_C) \end{aligned} \quad (10)$$

with $\bar{p} = (p + |\mathbf{B}|^2/2 + p_w)$, $p_w = (\sigma_D + 1)\rho Z^2/4$ and $\eta = 1 + \sigma_D \rho Z^2/(2B^2)$ for the considered case of transverse and axisymmetric turbulence. Equations (7) – (9) are identical to those of Usmanov et al. (2011), while the above form of the energy equation is derived in Appendix B. Furthermore, ρ is the mass density, $\mathbf{U}$ and $\mathbf{V} = \mathbf{U} - \boldsymbol{\Omega} \times \mathbf{r}$ denote the fluid velocity in the rest and corotating frame, respectively, $\mathbf{B}$ is the mean magnetic field, p is the scalar thermal pressure, $\mathbf{g} = (GM_\odot/r^2)\hat{\mathbf{r}}$ describes the Sun’s gravitational acceleration, and $\boldsymbol{\Omega} = \Omega \mathbf{e}_z$ is the Sun’s angular rotation speed with $\Omega = 14.71^\circ/\text{d}$ (Snodgrass & Ulrich 1990). The energy density $e = \rho U^2/2 + B^2/2 + p/(\gamma - 1)$ is used without both the gravitational potential and the turbulent energy component $\rho Z^2/2$, which are instead attributed by means of the right-hand sided source terms in Equation (10), see Appendix B. An adiabatic equation of state is used with $\gamma = 5/3$, while, due to the inclusion of Hollweg’s heat flux (Hollweg 1974, 1976) $\mathbf{q}_H = (3/4)p\mathbf{V}$, the effective value of the adiabatic index $\gamma_{eff} = 13/9$ is close to observationally inferred values (Totten et al. 1995).

We use spherical coordinates (r, ϑ, φ) with the origin being located at the center of the Sun. Thus, r is the heliocentric radial distance, $\vartheta \in [0, \pi]$ is the colatitude or polar angle (with the north pole corresponding to $\vartheta = 0$) and $\varphi \in [0, 2\pi]$ is the azimuthal angle.

The above sets of equations are both given in their normalized form, so that for instance no factors of 4π or μ_0 occur with the magnetic energy density.

CRONOS employs a semi-discrete finite-volume scheme with Runge-Kutta time integration and adaptive time-stepping, allowing for different approximate Riemann solvers. Although we make use of its conservative features by implementing as many terms as possible as divergence of fluxes, a number of source terms remain. In cases where source terms involve differentiation we apply second order accurate central finite differences. The solenoidality of the magnetic field is ensured via constrained transport, provided the magnetic field is initialized as divergence-free. Besides the code’s support of Cartesian, cylindrical, and spherical (including coordinate singularities) coordinates, it also allows for non-equidistantly spaced grids, e.g. a spatially varying Δr , as long as all coordinate planes remain orthongonal.

3. Model Validation

To validate our implementation we compare our results with those of Usmanov et al. (2011). In order to have an equivalent set of equations the following adaptations have to be made to Equations (1) – (3): Neglecting the Alfvén velocity and employing only the isotropization of newly born pickup ions as source for turbulence, i.e.

$$\langle \mathbf{z}^\pm \cdot \mathbf{S}^\pm \rangle_{pui} = \frac{\dot{E}_{pui}}{2} = \frac{1}{2} \frac{f_d U V_A n_H}{n_0 \tau_{ion}} \exp\left(-\frac{L_{cav}}{r}\right). \quad (11)$$

Here, $f_D = 0.25$ is the fraction of pickup ion energy transferred into excited waves, $n_H = 0.1 \text{ cm}^{-3}$ is the interstellar neutral hydrogen density, $\tau_{ion} = 10^6 \text{ s}$ is the neutral ionization time at 1 AU, $L_{cav} = 8 \text{ AU}$ is the characteristic scale of the ionization cavity of the Sun, and $n_{sw} = 5 \text{ cm}^{-3}$ is the solar wind density at 1 AU. Although neglected in the turbulence transport equations, here $V_A = B/\sqrt{\rho}$, and U is the solar wind speed.

The background solar wind results from an untilted dipole configuration for which the boundary conditions at 0.3 AU have been fitted to be close to the ones of Usmanov et al. (2011), as can be seen in Figure 1. Thus we have a tenuous and hot high-speed wind at

high latitudes, while the equatorial region is occupied by a dense and cold slow-speed solar wind. The magnetic field corresponds to a Parker spiral configuration with a change of sign at the equator, resulting in a flat current-sheet there. The turbulence quantities are set accordingly to higher values in the fast wind, decreasing to smaller values in the slow wind (see also Figure 2 for an overview).

Our boundary conditions approximate those used by Usmanov fairly well except for the transition of the magnetic field at the current sheet, which is much sharper in our case. The radial initialisation is also the same as Usmanovs.

The computational domain in this case covers the radial range from 0.3 AU to 100 AU with 300 cells of linearly increasing radial cell size $\Delta r \in [10, 230]R_{\odot}$. Rotational symmetry allows us to use just one active cell (plus ghost cells) covering the azimuth φ , and the polar angle is covered with 180 cells of uniform size. The simulation is advanced in time until a steady state is reached – which is basically the time that the slowest solar wind parcels need to reach the outer boundary. A quantitative comparison with the Usmanov results is presented in Figure 3. Shown are the radial variations of the large-scale quantities in the six left panels and the turbulence quantities in the right panels, respectively taken at colatitudes of 0° (solid line), 30° (dashed), 60° (dotted) and 90° (dashed-dotted).

Note that the red curves are not those shown in Usmanov et al. (2011), but have been obtained from A. Usmanov (priv. comm.) after some differences had been discovered: First, the temperature curve shown in their original paper is in disagreement with the respective curves for number density and pressure. Second, their implementation of the term $\hat{\mathbf{B}} \cdot (\hat{\mathbf{B}} \cdot \nabla)\mathbf{U}$ in spherical coordinates failed to include all geometrical source terms.

Our results are generally in good agreement with the newly obtained reference values, but some small deviations exist that will be addressed when briefly describing the results below: The magnetic field strength (top left) decreases as $1/r^2$ at the poles, where it is purely radial, while for lower latitudes the azimuthal component decreasing as $1/r$ becomes

dominant. Slight differences with regard to the reference case are present as a result of the different boundary conditions. This is more clearly visible in the panel for the Alfvén velocity (bottom left), however, the asymptotic values are in very good agreement. The total turbulent energy Z^2 (top right) decays gradually within about 10 AU, after which the turbulence generation via pickup ions becomes important and flattens the profiles. Since the pickup-ion source term is proportional to V_A there is a latitude dependence resulting in a later onset of profile flattening towards high latitudes. The match between the results is excellent in the high-speed wind region, while the results at the equator beyond 10 AU are off. This is because of our constrained transport scheme involving staggered grids, where the magnetic field is stored on respective cell surfaces and the other quantities at cell centers. The current sheet is implemented best with an even number of cells in polar angle so that there is actually no cell in which $B = 0$. This in turn gives no zero pickup ion term (by means of a non-vanishing V_A entering), which explains the higher values for the total turbulent energy at the equator. The cell-centered quantities are actually located at half-integer values, so that in Figure 3 our results are respectively offset by a half degree from those of Usmanov, which can also be expected to give some minor deviations.

The dissipated energy is transferred into heat so that the temperature (or pressure, related through number density (middle panels)) is higher than would be the case for an adiabatically cooling wind for given γ . This is also reflected in slightly higher terminal radial velocities (left center), where the equatorial wind is faster than in the reference case because of the dissipated higher turbulent energy as mentioned above. The cross-helicity gives the ratio between inward and outward propagating modes. As we have an inwardly directed mean magnetic field in the considered upper hemisphere, only the anti-parallel $\mathbf{z}^+$ modes can escape the sub-Alfvénic region below about $20R_\odot$, so that σ_C is close to unity. As new turbulence – specifically also parallel propagating modes $\mathbf{z}^-$ – are generated in the outer-heliosphere the ratio between the modes goes to zero. The interesting feature of

increased cross-helicity between 1-10 AU is due to the additional mixing term $\hat{\mathbf{B}} \cdot (\hat{\mathbf{B}} \cdot \nabla) \mathbf{U}$. This term simplifies for a constant radial solar wind speed and Parker spiral magnetic field, resulting in $\hat{\mathbf{B}} \cdot (\hat{\mathbf{B}} \cdot \nabla) \mathbf{U} \approx (B_\varphi/B)^2 (U/r)$ so that via B_φ a latitude dependence is introduced. The effect of this term is to inhibit equipartition between forward and backward propagating modes by preferring the generation of forward propagating modes, before the onset of additional turbulence generation via pickup-ions beyond 10 AU becomes dominant. Meanwhile, the deviations with respect to the reference results for the 60° curve are due to a lower value of magnetic field strength here as described above. The rate of dissipation is controlled by the correlation length λ that initially rises gradually to a maximum depending on latitude and then decreases again as a result of the interplay between the right-hand terms of Equation (3). The breaks at about 10 AU are again caused by the pickup-ion term, indicating that sources of turbulence tend to decrease the correlation length, which will also be addressed when including shear driving below.

The overview presented in Figure 2 also shows the ratio of turbulent magnetic field to mean magnetic field $\delta B/B$ as an additional quantity, which can be calculated via

$$\delta B^2 = \langle b^2 \rangle = \frac{\rho Z^2}{2} (1 - \sigma_D) \quad (12)$$

for given (constant) σ_D . This quantity bears great importance for the transport of energetic particles in the heliosphere as it is a measure for the efficiency of diffusion (see, e.g., Manuel et al. 2014). The results show that although the turbulent energy is low in polar regions, the magnetic field strength there diminishes more rapidly and results in high diffusion levels that gradually decrease towards the ecliptic.

4. Model extension

It is stated in Usmanov et al. (2011) that their model does not seem to require additional source terms to account for the effects of turbulence driven by shear. However,

as acknowledged in Usmanov et al. (2014), this is not the case. Furthermore, this is also pointed out in Appendix A of Zank et al. (2012), where it is noted that these kind of turbulence transport models do not capture turbulence driven by shear terms due to the imposed structural similarity closure relations, such that instead these terms have to be explicitly accounted for via additional source terms. Usmanov et al. (2014) incorporated shear effects with an eddy viscosity approximation, which we intend to adopt in our implementation for future studies as well. For now we include the required terms in a similar fashion as in Zank et al. (1996) and Breech et al. (2008), but in improvement to these models we compute the gradients in the solar wind speed self-consistently from the background field via

$$\langle \mathbf{z}^{\pm} \cdot \mathbf{S}^{\pm} \rangle_{sh} = \frac{1}{2} Z^2 \underbrace{C_{sh} \left| \frac{1}{r} \left(\partial_{\vartheta} + \frac{1}{\sin(\vartheta)} \partial_{\varphi} \right) |\mathbf{U}| \right|}_{\hat{C}_{sh}}. \quad (13)$$

We use a value of $C_{sh} = 0.5$, which is commonly taken at high latitudes (no shear) to match observational results (Breech et al. 2005). Previous studies (e.g. Breech et al. (2008); Engelbrecht & Burger (2013)) have estimated typical values for gradients in the solar wind speed and absorbed them in the definition for $\hat{C}_{sh}$ so that it is varying with position. Here, we treat C_{sh} as a constant and get an equivalent expression for $\hat{C}_{sh}$ as indicated in Equation (13).

Figure 4 shows a comparison of simulations using the above setup with and without the shear term in meridional slices at different heliocentric distances (solid: 1AU, dashed: 10AU). The black (red) lines show the results (not) including the shear term, while the blue lines are taken from Breech et al. (2008). As expected, differences arise mainly in the transition region between slow and fast solar wind (at about $70 - 80^\circ$), which gives rise to shear. Considering the 1AU slices (solid lines) first, it can be seen that the shear term leads to (otherwise absent) enhancements in turbulent energy, which are comparable to the enhancements in the Breech results, where the latter are at slightly lower colatitudes due

to different modeling of the transition region. Meanwhile, the cross-helicity is now strongly decreased in this region due to the newly generated turbulence, which is also qualitatively visible in the Breech data, who however used lower boundary values for the cross-helicity so that it is initially lower. While the correlation length is enhanced in the Breech model, it is decreasing in the shear region in our model. This is due to our inclusion of the term in the respective Equation (3) for the correlation length, where as mentioned above with regard to the pickup-ion source term, the generation of turbulence leads to decreased correlation lengths. The shear term is absent in the evolution equation for λ in the Breech model, where it is assumed that shear drives turbulence at all scales. As our starting point for the turbulence transport equations is the model by Zank et al. (2012), who include this term also in the correlation length equation, we will maintain it as well. While at 1AU the resulting temperature enhancement is similar to the one in Breech (different boundary values again cause an overall lower temperature here), the results at larger radial distances show some differences: in our model the turbulent energy just barely peaks at the transition region and the temperature is only slightly enhanced as well, whereas in the Breech model the peak becomes ever more pronounced. This is the result of an interplay between the generation of turbulence due to shear, which weakens with radial distance, and its dissipation controlled by the correlation length. A more detailed study addressing the effect of shear on the correlation length might be in order to clarify proper modeling. We want to mention though that Ulysses data for solar minimum conditions (plate 6 in McComas et al. 2000) do not seem to show evidence for a strongly enhanced temperature in this region.

The model can be readily extended to include terms involving the Alfvén velocity. We maintain the same boundary conditions as before and the results are compared to the ones neglecting Alfvén velocity in Figure 5. The effect on the large-scale quantities is negligible and, thus, not shown. The turbulence quantities also show only minor differences:

The turbulent energy tends to be up to about 1.5 times higher at high latitudes and the correlation length is almost unaffected. Near the equator the results are almost identical for all quantities. The normalized cross-helicity also tends to stay about 10% larger when including the additional terms. These deviations occur close to the inner boundary, where the Alfvén speed is highest, and the resulting higher cross-helicity values are convected to larger radial distances. This effect is expected to be more prominent when moving the inner boundary closer to the Sun, as will be done in the subsequent section. For an inner boundary at about 0.3 AU as considered so far, the neglect of the Alfvén velocity terms is therefore justifiable to some extent, but the effect of enhanced cross-helicity could be incorporated in models neglecting these terms by increasing the boundary values accordingly.

5. Application to the inner heliosphere and transient structures

The turbulence transport equations (1) – (3) now also accommodate the effect of shear driving by means of Equation (13) so that the model can be applied to solar wind transients with arbitrary gradients in solar wind speed. In Section 5.2 we apply the above set of equations to a ”toy-model” CME and study the results in comparison to the model not including turbulence. Furthermore, including terms involving the Alfvén velocity enables us to move the inner boundary closer to the Sun. In the following the inner boundary is located at 0.1 AU, which is usually just beyond the Alfvén critical radius. This is a suitable choice for the following reasons: (i) The turbulence transport model is only partly appropriate for sub-Alfvénic regions such as the corona or the heliosheath. Specifically, the dissipation terms are subtle to model for low-beta regions and still need to be properly adapted for such cases (G. Zank, priv. comm.; see also Zank et al. (2012)). (ii) Coronal MHD models are much more complex and are computationally quite expensive. A simplified model of

the corona is the WSA model that is frequently used to derive boundary conditions for heliospheric MHD simulations such as in our previous work (Wiengarten et al. 2014) or in the ENLIL code (Odstreil et al. 2004), which is in operation at the space weather prediction center. Here, the interface between WSA and MHD is usually located at 0.1 AU, so that especially for future purposes, where we will aim to perform the simulations with input from the WSA model, this would be the obvious choice. (iii) When applying our model to interplanetary disturbances such as CMEs, it is desirable to catch as much of their evolution self-consistently, which demands to put the inner boundary as close to the Sun as possible. Given the above caveats, this currently cannot be done in a more self-consistent manner by triggering a reconnection event at the coronal base (as in, e.g., Manchester et al. (2005); Kozarev et al. (2013)), but instead an estimate for CME properties at intermediate distances has to be found (see Section 5.2).

In what follows the simulation domain is restricted to the radial extent $r \in [0.1, 1.2]$ AU and we do not cover the polar coordinate singularities to avoid small time steps. Therefore, $\vartheta \in [0.1, 0.9]\pi$. Furthermore, to save computing time the azimuthal extent is restricted to $\varphi \in [0.5, 1.5]\pi$ as the center of the CME will be located at $[\vartheta, \varphi]_{CME} = [0.5, 1]\pi$, and during its subsequent evolution it does not reach the outer azimuthal boundaries in this setup. The applied resolution is $[\Delta r, \Delta \vartheta, \Delta \varphi] = [0.5R_{\odot}, 1^{\circ}, 1^{\circ}]$ corresponding to gridcells per direction as $[N_r, N_{\vartheta}, N_{\varphi}] = [480, 144, 180]$.

5.1. Quiet Solar Wind

We first describe the quiet background solar wind, into which a CME will be injected. CMEs occur more frequently during periods of solar maximum, which is characterized by a highly tilted current sheet and disappearance of the region of fast polar solar wind, so that

instead a slow wind is present at all latitudes. For simplicity, and since we leave out the polar coordinate singularity, we resort to a simple flat current sheet. This also allows us to keep the analysis of the results relatively tractable.

We estimated respective boundary conditions at 0.1AU for the large-scale quantities from typical values used in our previous work employing the WSA model (Wiengarten et al. 2014). The boundary values and the resulting radial evolution at selected colatitudes are shown in Figure 6 (black lines), where for orientation the findings of Usmanov et al. (2011) (red lines) from 0.3 AU onwards are shown as well. The resulting configuration is similar to the equatorial slow speed region from the previous section but with slightly enhanced speeds, higher temperature, and lower density, while the magnetic field is the same as before. For the turbulent energy and the correlation length we use boundary values that also give similar radial profiles as shown previously, but for the cross-helicity it should be assumed that just beyond the Alfvénic critical radius there are almost only forward propagating modes, so that $|\sigma_C|$ should be close to unity and we choose $|\sigma_C|(0.1AU) = 0.95$. As shown above, including the Alfvén velocity terms in the model tends to retain cross-helicity values closer to unity, and since there are no additional sources of turbulence so far the cross-helicity now remains larger at and beyond 0.3 AU in contrast to the Usmanov values.

5.2. Perturbation by a CME

5.2.1. Initialization

As the computational domain does not extend down to the corona, where CMEs are thought to be triggered via reconnection events, we do not use an injection scheme that inserts out-of-equilibrium flux ropes as done in coronal models (e.g., Manchester et al. 2005; Kozarev et al. 2013), but we estimate typical CME properties at the intermediate distance of $r_0 = 0.1$ AU from simulations performed by Kleimann et al. (2009). We find that the

shape of the CME in these simulations remains similar to the initialized one, as was also reported in previous studies and motivated the Cone model (Zhao et al. 2002), which is also used to initiate CMEs in the ENLIL setup (Odstrcil et al. 2004). The almost radial propagation of CMEs through the corona allows for an easy geometrical estimation of its properties a few solar radii away from the Sun. While for space weather forecasting studies such estimates are based on observations, here we consider a "toy model" with idealized properties. We first define the normalized angular distance of a given point $[\vartheta, \varphi]$ on the spherical inner boundary to the center of the CME onset site $[\vartheta, \varphi]_{cme} = [0.5, 1]\pi$ as

$$a = \arccos[X_{0,cme} \sin(\vartheta) \cos(\varphi) + Y_{0,cme} \sin(\vartheta) \sin(\varphi) + Z_{0,cme} \cos(\vartheta)]/\delta_{cme} , \quad (14)$$

where $[X, Y, Z]_{0,cme} = [\sin(\vartheta_{cme}) \cos(\varphi_{cme}), \sin(\vartheta_{cme}) \sin(\varphi_{cme}), \cos(\vartheta_{cme})]$ are the Cartesian coordinates of the site's center, and $\delta_{cme} = \pi/8$ denotes its angular radius. Within this circular patch characterized by $a(\vartheta, \varphi) \leq 1$, we raise the large-scale fluid quantities during the CME initialisation according to $[v_r, T, n]_{cme} = [8v_r, 4T, 1.5n]_{quiet} \cos(0.5\pi \cdot a)f(t)$, so that the enhancement peaks at the center and decreases towards the edges of the circular area. For the time dependence we choose a linearly decreasing function $f(t)$ from maximal values at t_{cme} back to quiet values at $t_{cme} + \delta t_{cme}$ with a duration of $\delta t_{cme} = 5t_0$, where our normalization value for time $t_0 = 3191s$. Furthermore, the onset time $t_{cme} = 200t_0$ is chosen as such that the initial quiet conditions have reached steady-state.

Although the magnetic field strength could be simply raised as the other quantities, this would not change the fields topology (Parker spiral), which we assume to be affected qualitatively by the CME's onset. We therefore prescribe an additional strong B_ϑ component as to get field-lines wrapping around the central region of the CME. To preserve the solenoidality constraint we directly prescribe the vector potential

$$\mathbf{A} = \begin{pmatrix} A_r \\ A_\vartheta \\ A_\varphi \end{pmatrix} = \begin{pmatrix} 0 \\ -B_0 r_0^2 \sin(\vartheta)(\varphi/r + \Omega/V_r) \\ -B_{0,cme} r_0 \cos(0.5\pi \cdot a)f(t) \end{pmatrix} , \quad (15)$$

where A_θ gives rise to the Parker spiral magnetic field, while A_φ results in the desired field lines wrapping around the CME (see Figure 7).

Meanwhile, we leave the turbulence quantities at the quiet solar wind boundary values. This is probably not a realistic assumption as the evolution in the sub-Alfvénic region should have an impact on the turbulence quantities as well. However, on the one hand there is little to no observational data of turbulence associated with CMEs this close to the Sun, and on the other hand, prescribing respective estimates as boundary conditions for the turbulence different from the quiet wind ones would make it more difficult to analyse the self-consistent evolution of these quantities beyond 0.1 AU, i.e. the influence of different boundary conditions and the evolution due to the governing equations would be impossible to disentangle.

5.2.2. Results and impact on turbulence quantities

An overview of the resulting 3D structure is shown in Figure 7. The field lines show the typical Parker spiral pattern far away from the CME, while close by they wrap around it. The CME can be partitioned into a compact central core region containing the high speed ejecta and a surrounding sheath region bounded by a shock driven by the CME. Due to the wealth in structure involved, we show results in 2D slices. First, we present meridional slices at $\varphi = \pi$ in Figure 8 so that they coincide with the azimuthal symmetry axis of the *initial* CME. The evolution in time is available as a movie in the supplementary material. Here, we show an adapted snapshot of the movie at $t_{ss} = 32.5t_0$ after initialization, which is the time at which the sheath region reaches 1 AU. The core and sheath region are most clearly seen in the large scale quantities (top row), but in particular in the radial velocity data, whereas in most of the quantities more complex structures are visible as well. In

general, structural variations occur mainly close to or within the elongated core region, while the almost circular sheath region is rather homogeneous in comparison. The sheath region is characterized by modest enhancements compared to the quiet conditions (visible beyond ≈ 1 AU) in density and magnetic field strength, while strong enhancements of $v_{r,sheath} \approx 700$ km/s and $T_{sheath} \approx 10^7$ K are found. The turbulent energy is also increased in this region, and also more so than the magnetic field strength, which follows from the visible enhancements in $\delta B/B$. The cross-helicity is slightly reduced, while the correlation length seems to exhibit almost no changes within the sheath region.

The core region partly overlaps with the current sheet affected equator. The current sheet is not ideally resolved, which would require adaptive mesh refinement, which, however, is not yet available in the CRONOS framework. Therefore, close to the current sheet we get strips of increased or depleted values that are overestimated in this model, but this does not affect the results offset from the equator too much.

While the sheath region is clearly discernible and has the same extent in all quantities, the core region is not similar in all quantities. The patch containing the highest velocity values reflects different behavior in the other quantities, where basically two regions can be distinguished: On the one hand there is a compression at the leading edge, also towards higher latitudes, with respective elevations in magnetic field strength, density, and turbulent energy, while on the other hand a rarefaction region trails the core, where depleted values are present. Besides these compressional effects there is clearly a distinct band of high turbulent energy due to shear around the edges of the high-speed central region. Respective structures are also visible in the panels for the correlation length and for the cross-helicity, where the latter is generally speaking closer to zero in most parts affected by the CME but also shows some additional structure, probably due to the complex magnetic field geometry. Finally, the panel for $\delta B/B$ reveals enhanced values in the sheath and around the core region, while the rarefaction region exhibits reduced turbulence levels. The respective

effects on the perpendicular and parallel mean free path of energetic particles is twofold, as the former is proportional to $\delta B/B$, while the latter is antiproportional to it. This can lead to counterintuitive results, where the presence of enhanced turbulence can even facilitate the transport of energetic particles as found by Guo & Florinski (2013) for CIRs.

While the meridional slices are symmetric with respect to the equatorial current sheet, this cannot be expected for azimuthal slices because of the symmetry breaking in the spiral structure of the magnetic field. Figure 9 shows respective results in azimuthal slices at $\vartheta = 85^\circ$, where this colatitude is chosen in order to show the behavior not directly at the current sheet, whose influence is overestimated in this model. These slices are oriented in accordance with the orientation in Figure 7. From the field lines shown there, it is clear that the magnetic field topology is different at the upper edge of the CME, where the field lines are compressed in a sense according to the initial bending direction of the Parker spiral, as compared to the lower edge where field lines are compressed in a sense opposite to the spiral bend. While many features remain similar to the ones described above for the meridional perspective, there are some additional features due to the symmetry breaking: The core region’s tail is bent towards the lower edge, while the sheath region is rather unaffected, i.e. remains quite symmetric in the hydrodynamic quantities (V_r, T, n) , but as discussed above the magnetic field compression in the sheath region is stronger at the upper edge, which also affects the turbulence quantities: At the upper edge of the core region there is an additional feature of reduced cross-helicity and enhanced turbulence, which is also reflected by a respective feature in temperature, whereas these structures are absent at the lower edge. A striking azimuthal structure for the diffusion levels is found, as the upper edge of the CME including the sheath region there show relatively small values, while towards the nose and the lower edge the diffusion levels are markedly higher. This represents an intriguing feature for a subsequent study of energetic particle propagation. To the best of our knowledge the observations of turbulence in or associated with CMEs

are rather limited and use data obtained at 1 AU (e.g. Ruzmaikin et al. 1997). The first study that derived quantitative estimates of magnetic turbulence levels near CME fronts was presented by Subramanian et al. (2009). Interestingly our findings are within the limits provided by these estimates.

5.2.3. *Impact of turbulence quantities on CME*

In the previous section we described the impact of disturbances in the large-scale flow via a CME on the turbulence quantities. We now study the effect of the turbulence quantities on the disturbed large scale flow by comparing the simulations discussed above with simulations where the turbulence is switched off, but the remaining setup is maintained.

We omit to show 2D slices as above since the results remain remarkably similar. Instead, Figure 10 shows radial profiles for the large-scale quantities at $\varphi = \pi$ and colatitudes of 85° (solid lines) and 75° (dashed lines) for the case with (black lines) and without turbulence (red lines). The deviations are very small in almost all regions, but a notable difference is the extent of the sheath region, which is marked, e.g., by the largest temperature values. The additional heating due to enhanced turbulence there results in a slightly more extended sheath region, but the effect can be considered small enough so that it is negligible for general CME propagation studies.

6. Summary and Outlook

In this paper we presented our implementation of turbulence transport coupled to the Reynolds-averaged ideal MHD equations in the framework of the CRONOS code. We followed the work of Usmanov et al. (2011) and validated our findings by comparing results with these authors’ findings. Their original model was extended to be applicable to regions of solar wind speeds that do not have to greatly exceed the Alfvén speed, which we achieved by simplifying the more general turbulence transport equations of Zank et al. (2012). It was shown that beyond radial distances of 0.3 AU the neglect of such terms is usually justified, but including them results in a slower decrease of normalized cross-helicity values, i.e. the generation of backward propagating modes is somewhat inhibited. This effect is stronger when moving the inner boundary of the simulations closer to the Sun, where the Alfvén speed is no longer small compared to the solar wind speed. Some additional terms that were inappropriately absent in the Usmanov et al. (2011) model have also been included in the present work: (i) the effect of turbulence driven by shear was introduced via respective ad-hoc terms, whose strength was estimated from comparisons with the work of Breech et al. (2008). Such an ad-hoc approach has to be taken because the structural similarity assumption, commonly made to achieve closure in the turbulence transport equations, prevents the self-consistent formulation of shear driving. Recently, Usmanov et al. (2014) removed this constraint by employing an eddy-viscosity approximation, which we plan to include in the future as well. (ii) The mixing term $\hat{\mathbf{B}} \cdot (\hat{\mathbf{B}} \cdot \nabla)\mathbf{U}$ was now correctly implemented that results in a (latitude-dependent) effect on the normalized cross-helicity, which is now even increasing towards about 10 AU, after which turbulence driven by ionization of pick-up ions becomes dominant and results in equipartition between forward and backward propagating modes.

While most previous studies of turbulence in the solar wind use prescribed solar wind conditions such as a constant wind speed and a simple Parker spiral magnetic field, our

approach allows for the self-consistent evolution of turbulence in a time-dependent and disturbed solar wind. Together with our extension towards non-highly-super-Alfvénic solar wind speeds, we are therefore able to move the inner boundary of our simulations closer to the Sun and consider the effects of transient structures on the turbulence quantities. While the effect of CIRs was already addressed in previous studies (Usmanov et al. 2012, 2014), we concentrate on CMEs, here, by using an injection scheme similar to the Cone model (Zhao et al. 2002), estimating typical CME properties at intermediate solar distances. Instead of trying to recreate a specific observed CME, we consider a relatively easy toy-model kind of scenario to study general effects and reserve a more detailed event study with respective comparison to spacecraft data for future work. While the large-scale quantities show typical structures such as a core and sheath region of the CME as found in previous studies (e.g. Manchester et al. 2005; Kozarev et al. 2013), here for the first time, we show the respective 3D structure of turbulence quantities of CMEs. These show enhanced turbulence levels and reduced cross-helicity values caused by the CME. Azimuthal symmetry is broken by the disturbed magnetic field and results in azimuthally varying diffusion levels, which will provide an interesting feature to study with energetic particle propagation models. We also investigated possible back reactions of turbulence on the large-scale flow by comparing with identical simulations save for the inclusion of turbulence. We find a slightly larger CME sheath region due to additional heating via the turbulent cascade, but in general the effect on the propagation of the CME is negligible and, therefore, does not have to be incorporated in models interested in the large-scale flow only.

Besides the future directions mentioned above, we will in a forthcoming study especially focus on implementing the full set of turbulence transport equations of Zank et al. (2012), which allow for a variable energy difference σ_D (thus far assumed to be constant) and different correlation lengths for the forward and backward propagating modes as well as for the energy difference, whereas so far a single correlation length was adopted. We

also plan to explore the possibility to include two component turbulence (Oughton et al. 2011). Furthermore, the background solar wind can be modeled more realistically with observationally based boundary conditions derived with the WSA model as reported in our previous work (Wiengarten et al. 2014), with which we will be able to model inner-heliospheric conditions for the background solar wind and associated turbulence. Both can then be directly compared to spacecraft observations and subsequently will serve as input to energetic particle propagation models.

Many thanks are in order to A. Usmanov, G. Zank and A. Dosch for fruitful discussions. Financial support for the project FI 706/8-2 (within Research Unit 1048), as well as for the projects FI 706/14-1 and HE 3279/15-1 funded by the Deutsche Forschungsgemeinschaft (DFG), and FWF-Projekt I1111 is acknowledged.

A. Turbulence transport equations

The turbulence transport equations used in Usmanov et al. (2011) can be derived from the more general model of Zank et al. (2012) with the simplifying assumptions of a single correlation length $\lambda = \lambda^\pm = \lambda_D/2$ and a choice of the structural similarity parameters $a = 1/2, b = 0$ corresponding to axisymmetric turbulence along the mean magnetic field direction, i.e. $\hat{\mathbf{n}} = \hat{\mathbf{B}}$. In not neglecting the Alfvén velocity and considering the co-rotating frame of reference we get from equations (37), (38) and (35) of Zank et al. (2012):

$$\begin{aligned} \partial_t Z^2 + \mathbf{V} \cdot \nabla Z^2 + \frac{Z^2}{2} \nabla \cdot \mathbf{U} - \mathbf{V}_A \cdot \nabla (Z^2 \sigma_C) + Z^2 \sigma_C \nabla \cdot \mathbf{V}_A \\ + Z^2 \sigma_D \left(\frac{\nabla \cdot \mathbf{U}}{2} - \hat{\mathbf{B}} \cdot (\hat{\mathbf{B}} \cdot \nabla) \mathbf{U} \right) \\ = - \frac{2Z^3 f^+(\sigma_C)}{\lambda_{Zank}} + \langle \mathbf{z}^+ \cdot \mathbf{S}^+ \rangle + \langle \mathbf{z}^- \cdot \mathbf{S}^- \rangle \end{aligned} \quad (\text{A1})$$

$$\begin{aligned} \partial_t (Z^2 \sigma_C) + \mathbf{V} \cdot \nabla (Z^2 \sigma_C) + \frac{Z^2 \sigma_C}{2} \nabla \cdot \mathbf{U} - \mathbf{V}_A \cdot \nabla Z^2 + Z^2 (1 - \sigma_D) \nabla \cdot \mathbf{V}_A \\ = - \frac{2Z^3 f^-(\sigma_C)}{\lambda_{Zank}} + \langle \mathbf{z}^+ \cdot \mathbf{S}^+ \rangle - \langle \mathbf{z}^- \cdot \mathbf{S}^- \rangle \end{aligned} \quad (\text{A2})$$

$$\begin{aligned} \partial_t \lambda_{Zank} + \mathbf{V} \cdot \nabla \lambda_{Zank} \\ = \frac{2Z f^+(\sigma_C)}{\sqrt{1 - \sigma_C^2}} - \frac{\lambda_{Zank}}{Z^2} \left(\frac{\langle \mathbf{z}^+ \cdot \mathbf{S}^+ \rangle (1 - \sigma_C) + \langle \mathbf{z}^- \cdot \mathbf{S}^- \rangle (1 + \sigma_C)}{1 - \sigma_C^2} \right), \end{aligned} \quad (\text{A3})$$

with $f^\pm = \sqrt{1 - \sigma_C^2} [\sqrt{1 + \sigma_C} \pm \sqrt{1 - \sigma_C}]$ where the following moments of the Elsässer variables $\mathbf{z}^\pm := \mathbf{u} \pm \mathbf{b}/\sqrt{\rho}$ ($\mathbf{u}$ and $\mathbf{b}$ denoting the fluctuations about the mean fields $\mathbf{U}$ and $\mathbf{B}$) are used:

$$Z^2 := \frac{\langle \mathbf{z}^+ \cdot \mathbf{z}^+ \rangle + \langle \mathbf{z}^- \cdot \mathbf{z}^- \rangle}{2} = \langle u^2 \rangle + \langle b^2/\rho \rangle (= E_T) \quad (\text{A4})$$

$$Z^2 \sigma_C := \frac{\langle \mathbf{z}^+ \cdot \mathbf{z}^+ \rangle - \langle \mathbf{z}^- \cdot \mathbf{z}^- \rangle}{2} = 2 \langle \mathbf{u} \cdot \mathbf{b}/\sqrt{\rho} \rangle (= E_C) \quad (\text{A5})$$

$$Z^2 \sigma_D := \langle \mathbf{z}^+ \cdot \mathbf{z}^- \rangle = \langle u^2 \rangle - \langle b^2/\rho \rangle (= E_D), \quad (\text{A6})$$

where the last equality is to clarify the change of notation from Zank et al. (2012). These authors absorbed a factor of 2 into the definition of the correlation length ($\lambda_{Zank} = 2\lambda_{def}$). To make use of the conservative scheme in the CRONOS code we rewrite the above equations in the fashion of $\partial_t X + \nabla \cdot \mathbf{F}_X = S_X$. Removing the factor 2 in the correlation length we obtain:

$$\begin{aligned} \partial_t Z^2 + \nabla \cdot (\mathbf{U}Z^2 + \mathbf{V}_A Z^2 \sigma_C) &= \frac{Z^2(1 - \sigma_D)}{2} \nabla \cdot \mathbf{U} + 2\mathbf{V}_A \cdot \nabla (Z^2 \sigma_C) + Z^2 \sigma_D \hat{\mathbf{B}} \cdot (\hat{\mathbf{B}} \cdot \nabla) \mathbf{U} \\ &\quad - \frac{\alpha Z^3 f^+(\sigma_C)}{\lambda} + \langle \mathbf{z}^+ \cdot \mathbf{S}^+ \rangle + \langle \mathbf{z}^- \cdot \mathbf{S}^- \rangle \end{aligned} \quad (\text{A7})$$

$$\begin{aligned} \partial_t (Z^2 \sigma_C) + \nabla \cdot (\mathbf{U}Z^2 \sigma_C + \mathbf{V}_A Z^2) &= \frac{Z^2 \sigma_C}{2} \nabla \cdot \mathbf{U} + 2\mathbf{V}_A \cdot \nabla Z^2 + Z^2 \sigma_D \nabla \cdot \mathbf{V}_A \\ &\quad - \frac{\alpha Z^3 f^-(\sigma_C)}{\lambda} + \langle \mathbf{z}^+ \cdot \mathbf{S}^+ \rangle - \langle \mathbf{z}^- \cdot \mathbf{S}^- \rangle \end{aligned} \quad (\text{A8})$$

$$\begin{aligned} \partial_t (\rho \lambda) + \nabla \cdot (\mathbf{U} \rho \lambda) &= \rho \beta \left[Z f^+(\sigma_C) - \frac{\lambda}{\alpha Z^2} (\langle \mathbf{z}^+ \cdot \mathbf{S}^+ \rangle (1 - \sigma_C) + \langle \mathbf{z}^- \cdot \mathbf{S}^- \rangle (1 + \sigma_C)) \right] \end{aligned} \quad (\text{A9})$$

Here, we have also made the following adaptations in order to obtain the slightly different dissipation terms used by Usmanov et al. (2011), whose model we use to validate our implementation: Involving the Karman-Taylor constants $\alpha = 2\beta = 0.8$ in the dissipation terms and neglecting additional factors of $1 - \sigma_C^2$ on the right hand side of equation (A3) (due to different modeling of this evolution equation, here it is taken from Breech et al. (2008)).

On neglecting Alfvén velocity terms and using only the isotropization of newly born pickup ions as source for turbulence, i.e. $\langle \mathbf{z}^\pm \cdot \mathbf{S}^\pm \rangle = \dot{E}_{pui}/2 = 0.5 f_d U V_A n_H / (n_0 \tau_{ion}) \exp(-L_{cav}/r)$, we arrive at the respective equations used in Usmanov et al. (2011).

B. Energy equation

The total energy density to be conserved in the coupled MHD – turbulence transport model is

$$E = \rho U^2/2 + p/(\gamma - 1) + B^2/2 - \rho G M_\odot/r + \rho Z^2/2 \quad (\text{B1})$$

accounting for the (rest-frame) kinetic, thermal, magnetic, gravitational, and turbulent energy densities. The resulting conservation equation can be obtained from carrying out a time derivative on (B1), which gives after some algebra (see Appendix A of Usmanov et al. 2011)

$$\partial_t E + \nabla \cdot [\mathbf{V}E + \mathbf{U}\bar{p} - \eta(\mathbf{U} \cdot \mathbf{B})\mathbf{B} + \mathbf{q}_H] = (\langle \mathbf{z}^+ \cdot \mathbf{S}^+ \rangle + \langle \mathbf{z}^- \cdot \mathbf{S}^- \rangle)\rho/2. \quad (\text{B2})$$

with $\eta = 1 + \sigma_D \rho Z^2/(2B^2)$, $\bar{p} = p + B^2/2 + p_w$ and $p_w = (\sigma_D + 1)\rho Z^2/4$. The current version of the CRONOS code does not provide the possibility to incorporate additional forms of energy densities with the original

$$e = \rho U^2/2 + p/(\gamma - 1) + B^2/2$$

obtained for the case of ideal MHD without any source terms. Therefore, in order to maintain a conservation of all involved forms of energies, we have to introduce respective source terms Q in the conservation equation of e

$$\partial_t e + \nabla \cdot [\mathbf{V}e + \mathbf{U}(p + B^2/2) - (\mathbf{U} \cdot \mathbf{B})\mathbf{B} + \mathbf{q}_H] = Q \quad (\text{B3})$$

such that on subtracting equation (B2) and solving for Q we obtain

$$\begin{aligned} Q = & -\partial_t(\rho Z^2/2) - \nabla \cdot [\mathbf{V}(\rho Z^2/2 - \rho G M_\odot/r)] \\ & - \nabla \cdot [\mathbf{U}p_w - (\mathbf{U} \cdot \mathbf{B})\mathbf{B}\sigma_D \rho Z^2/(2B^2)] + (\langle \mathbf{z}^+ \cdot \mathbf{S}^+ \rangle + \langle \mathbf{z}^- \cdot \mathbf{S}^- \rangle)\rho/2. \end{aligned} \quad (\text{B4})$$

After some lengthy algebra and involving equations (7) and (1) this gives

$$\begin{aligned} Q = & [Z^2 \sigma_C \nabla \cdot \mathbf{V}_A - \mathbf{V}_A \cdot \nabla(Z^2 \sigma_C)] \frac{\rho}{2} - \mathbf{U} \cdot \nabla p_w + \mathbf{U} \cdot (\mathbf{B} \cdot \nabla)[(\eta - 1)\mathbf{B}] \\ & + \frac{\rho Z^3 f^+(\sigma_C)}{2\lambda} - \rho \mathbf{V} \cdot \mathbf{g} \end{aligned} \quad (\text{B5})$$

where we also used the vector identity

$$\mathbf{U} \cdot (\mathbf{B} \cdot \nabla)[(\eta - 1)\mathbf{B}] = \nabla \cdot (\eta - 1)\mathbf{B}(\mathbf{U} \cdot \mathbf{B}) - (\eta - 1)\mathbf{B} \cdot (\mathbf{B} \cdot \nabla)\mathbf{U} . \quad (\text{B6})$$

Finally, on extracting a flux term viz.

$$\left[Z^2 \sigma_C \nabla \cdot \mathbf{V}_A - \mathbf{V}_A \cdot \nabla (Z^2 \sigma_C) \right] \frac{\rho}{2} = \nabla \cdot (Z^2 \sigma_C \mathbf{V}_A \rho / 2) - \rho \mathbf{V}_A \cdot \nabla (Z^2 \sigma_C) - Z^2 \sigma_C \mathbf{V}_A \cdot \nabla \rho / 2 \quad (\text{B7})$$

and adding Hollweg’s heat flux (Hollweg 1974, 1976) we get the final equation

$$\begin{aligned} \partial_t e + \nabla \cdot \left[e \mathbf{V} + (p + |\mathbf{B}|^2/2) \mathbf{U} - (\mathbf{U} \cdot \mathbf{B})\mathbf{B} - \mathbf{V}_A \rho Z^2 \sigma_C / 2 + \mathbf{q}_H \right] = \\ - \rho \mathbf{V} \cdot \mathbf{g} - \mathbf{U} \cdot \nabla p_w - \frac{Z^2 \sigma_C}{2} \mathbf{V}_A \cdot \nabla \rho + \frac{\rho Z^3 f^+(\sigma_C)}{2\lambda} \\ + \mathbf{U} \cdot (\mathbf{B} \cdot \nabla)[(\eta - 1)\mathbf{B}] - \rho \mathbf{V}_A \cdot \nabla (Z^2 \sigma_C) . \end{aligned} \quad (\text{B8})$$

C. The CRONOS code

The CRONOS code used in this study is a versatile code for the numerical solution of the MHD equations. The code is written in C++ and is fully MPI-parallel. Usage of C++ leads to a high modularity that allows changing core components at runtime or adding new features rather easily.

The code is of second order in space and time. Among the core components are a variety of approximate Riemann solvers that can be chosen by the user according to the model to be simulated. CRONOS solves hydrodynamical (HD) and magnetohydrodynamical (MHD) problems. The corresponding Riemann solvers included in CRONOS are HLL (see Harten et al. 1983), HLLC (HD only, see Toro et al. 1994) and HLLD (MHD only, see Miyoshi & Kusano 2005).

For MHD simulations the solenoidality of the magnetic field is ensured by using constrained transport (see Brackbill & Barnes 1980, who first applied it to MHD). For the HLL

solver the numerical electric field computation is consistently implemented as described in Kissmann & Pomoell (2012) (see also in Londrillo & del Zanna 2000, 2004; Ziegler 2011). For the HLLD we implemented the electric field computation as described in Gardiner & Stone (2005), who showed that a computation via a direct averaging of the fluxes resulting from the conservative form of the MHD equations can lead to instabilities.

Since CRONOS is optimised for highly compressible flows, the second-order reconstruction employs slope limiters that can be chosen by the user. Other limiters can be added easily to the simulation framework. Numerical problems are solved on an orthogonal grid, where Cartesian, cylindrical, and spherical coordinates are supported. For such a grid the cell size can be varied along each coordinated direction. The grid is specified by the user and is not changed during the simulation.

The code is used by supplying a simulation module that contains all relevant information for the simulation setup. Apart from the initial conditions, e.g. additional forces can be defined by the user. A feature extensively used in the present study is the option to solve other hyperbolic partial differential equations simultaneously with the system of MHD equations. For this, the specific fluxes of the additional differential equations can also be specified within the user module. In a similar fashion, other types of differential equations can be handled in parallel to the main solver by supplying the corresponding alternative solver. CRONOS offers a standard interface to specify the alternative solver. For the solution in parallel to the main solver an operator-splitting approach is implemented.

The CRONOS code has been applied in a range of different studies ranging from stellar wind simulations to accretion disc models (see Flaig et al. 2011). Verification of the code was done in the context of the different studies. In particular the numerical papers Kissmann et al. (2009) and Kissmann & Pomoell (2012) show that various HD and MHD standard problems are solved correctly by the code.

Fig. 1.— Boundary conditions at 0.3 AU (black lines) in comparison with those of Usmanov et al. (2011) (red lines).

Fig. 2.— Results in meridional slices for (top left to bottom right): magnetic field strength B , radial velocity V_r , temperature T , number density n , turbulent energy density Z^2 , normalized cross-helicity σ_C , correlation length λ , and turbulence levels $\delta B/B$.

Fig. 3.— Our results (black lines) in comparison with those of Usmanov et al. (2011) (red lines) for (top left to bottom right) magnetic field strength B , temperature T , turbulent energy Z^2 , radial velocity V_r , number density n , normalized cross-helicity σ_C , Alfvén velocity V_A , thermal pressure p , and correlation length λ .

Fig. 4.— Turbulence quantities and temperature in meridional slices at different heliocentric distances (solid: 1AU, dashed: 10AU). The black (red) lines show the results (not) including the shear term, while the blue lines are taken from Breech et al. (2008).

Fig. 5.— Results for the turbulence quantities with (black lines) and without (red lines) including the Alfvén velocity terms.

Fig. 6.— Results for the quiet solar wind at different colatitudes in the same format as Figure 3.

Fig. 7.— 3D visualization of CME with magnetic field lines. The center sphere is the inner boundary, while the computational domain is clipped at the equator and made opaque. The color coding is for radial speed and shows the sheath and core region of the CME (see text), while the whitish opaque shape is the contour of $V_r = 650$ km/s that shows the 3D extent of the core region of the CME. The time evolution as an animation of this figure is available in the supplementary material.

Fig. 8.— Results including turbulence at $t = 32.5t_0$ after CME injection in meridional slices at $\varphi = \pi$. The time evolution as an animation of this figure is available in the supplementary material.

Fig. 9.— Results including turbulence at $t = 32.5t_0$ after CME injection in azimuthal slices at $\vartheta = 85^\circ$. The time evolution as an animation of this figure is available in the supplementary material.

Fig. 10.— Comparison of large-scale quantities for simulations with (black) and without turbulence (red).
